INTRODUCTION

1.1. RESEARCH QUESTIONS

Main question:

How can the nD-Laplace algorithm be applied in training privacy-preserving clustering algorithms on distributed n-dimensional data?

1. RQ1: How can 2D-Laplace be used to protect the data privacy of 2-dimensional data which is employed for training clustering algorithms?

2. RQ2: How can 3D-Laplace be extended to protect the data privacy of n-dimensional data which is employed for training clustering algorithms?

3. RQ3: What is the impact of different privacy budgets, dataset properties, and other clustering algorithms on the research conducted for research question 2?

2

LITERATURE REVIEW

This chapter lays out the theoretical foundation of this work. To review the past literature, it is first necessary to gather the required knowledge for it.

2.1. DIFFERENTIAL PRIVACY

Explain general notion of privacy

MATH SYMBOLS

$K(x)(Z)$ Randomization method for $x \in X$ and output $z \in Z$..

$Pr(K(x_i) \in (Z))$ Probability of reporting $x \in X$ for $z \in Z$.

X Set of locations for a user. (R^2).

Z For every $x \in X$ a perturbed location $z \in Z$ is reported..

ϵ Privacy budget.

$$\text{Pr}(K(X_1) \in Z) \leq e(\epsilon) * \text{Pr}(K(X_1) \in Z)$$

Figure 2.1: Randomization function K gives ϵ-differential privacy for all elements in D_1 and D_2 if they differ at most one element. [Dwork, 2006]

The privacy budget ϵ determines the amount of noise that is added.

2.1.1. LAPLACE ALGORITHM

One way to achieve ϵ-DP is using sampling noise from the Laplace or Gaussian distributions.

Explain gaussian / laplace distributions

The noise is then based on the sensitivity of a function f. This is the maximal possible change when adding or removing a single record [Dwork, 2006; Friedman and Schuster, 2010].

$$\Delta f = max_{D_1,D_2}||f(D_1) - f(D_2)|| \tag{2.1}$$

Explain differential privacy implementation with La place distribution

2.1.2. LOCAL DIFFERENTIAL PRIVACY
2.1.3. GEO-INDISTINGUISHABILITY
2.1.4. EVALUATION METHODS

It is possible to evaluate and measure the impact of the noise between two distributions by calculating the error between the non-private and private data [Xiong et al., 2020]. Two metrics that are proposed by the same study are Mean Squared Error (MSE) and Mean Average Error (MAE). These metrics can be used to calculate the error between X and the perturbed dataset Z.

Just as it is possible to measure the utility, this can also be done with privacy. When performing a privacy algorithm, it can be proven whether a method meets the privacy requirements. These are metrics such as ϵ-differential-privacy (2.1) and ϵ-geo-indistinguishability (see next chapter 3.1). Although these methods give an idea of privacy, it can only be "yes" or "no". Furthermore, it can give a distorted image, since a chance of 70% also gives a "yes" according to the definition of geo-indistinguishability [Oya et al., 2017]. In other words, to gain more insight into the amount of privacy (such as with MSE or MAE), other metrics are needed.

For this reason, Oya et al. introduced a metric for geo-indistinguishability that makes it possible to give percentages in their study [Oya et al., 2017]: As an example, an adversary is given that guesses between two locations: $x \in X$ and $x' \in X$.

$$p_e(x, x', z) \leq p_e^* = \frac{1}{1 + e^{e * d(x,x')}} \tag{2.2}$$

Where privacy level p_e^* is the lower bound of the probability of an adversary guessing correctly. The method is called ϵ-geo-indistinguishability as error. Based on this metric, it can be calculated that an adversary has an average of 90% chance to guess a location correctly. In that case, the algorithm would be ϵ-geo-indistinguishability, but in practice not.

2.2. CLUSTERING
2.2.1. METHODS

Describe each clustering method with important parameters that could influence the outcome

K-MEANS

The KMeans algorithm is based on the algorithm of Loyd et al. . The starting point is determined randomly by choosing k number of centroids. Each point is then assigned to a centroid based on the Euclidean distance. A new centroid is then determined based on the cluster average. This is repeated until the given number of iterations is reached or until the results are stable.

Source

Choosing K: The most important parameter of the K-Means algorithm is the value of k. This value determines the number of clusters to consider and has a big influence on the results [Ahmed et al., 2020].

The first method is called an "elbow" plot [Kodinariya and Makwana, 2013]. This method can be used to determine the best k by applying the algorithm multiple times and estimating the best k.

Figure 2.2: Illustration of determining k using the "elbow" method [Kodinariya and Makwana, 2013]

In this situation, a Silhouette plot can be used to determine the k. This method uses calculates the Silhouette coefficient for each cluster [SAPUTRA et al., 2020]. It takes into consideration the separation and cohesion of the cluster. The plot can then be made by plotting the silhouette coefficient on the y-axis and k on the x-axis [SAPUTRA et al., 2020]. Then the K with the highest coefficient can be selected based on that.

Another popular method is the Gap statistic method [Yuan and Yang, 2019]. It compares the total within-cluster variation for different values of k with their expected values under a null reference distribution of the data [Tibshirani et al., 2001]. A practical appliance of this method uses a line plot for comparing the k-value and gap value [Yuan and Yang, 2019]. Based on the visual change of the line, someone is be-able to select the best k.

All in all, there is no fixed method to choose a good k for K-means. The elbow method is common in the existing literature and is very popular due to its simplicity. However, one disadvantage is that it can be difficult to determine the "elbow" point, as it is not always present [Kodinariya and Makwana, 2013]. In that case, the silhouette method or gap statistic method can be chosen, with the algorithm for silhouette being the most obvious choice due to its simplicity.

AFFINITY PROPAGATION
Affinity Propogation (AP) is an algorithm that clusters data points by iteratively passing messages between them. Each point sends and receives messages about the attractiveness of other points as cluster centers (exemplars) and the suitability of itself as a center [Keller et al., 2021]. The method was introduced by Frey et al. and does not require any hyperparameters [Frey and Dueck, 2007]. Still, there are important properties that could potentially impact the clustering [Wang et al., 2007].

Choosing preference(p): Indicates the preference that a data point is selected as cluster center [Wang et al., 2007]. It highly influences the number of clusters, a high one would lead to more clusters and a small one to less [Moiane and Machado, 2018]. A good choice depending on the data is to set the p to the median of all data similarities [Wang et al., 2007]. But, the effectiveness of this could highly be influenced based on the dataset. To validate if the preference is correctly set, it is possible to analyze the silhouette coefficient [Moiane and Machado, 2018].

Choosing damping factor($lam \in [0,1]$): The damping factor is used to improve the stability (convergence) of the algorithm [Wang et al., 2007]. By default, this value is 0.5 and can be increased to 1 to reduce the impact of numerical oscillations. This can be applied manually, by re-running the algorithm and finding the optimal or just being increased. However, both approaches take a lot of time, especially for bigger datasets [Wang et al., 2007].

To conclude on this, damping is important if big datasets are considered. However, this research does not use large datasets or consider time complexity as a metric. The preference on the other hand could influence the results a lot. For this, the silhouette coefficient can be evaluated to choose the best option. In general, it should be sufficient to take the median.

DBSCAN
Density-based spatial clustering of applications with noise (DBSCAN) was introduced by [Ester et al.] and works by drawing a radius (neighborhood) around data points. It then groups all points within this radius as clusters. The main advantage is its ability to find arbitrarily shaped clusters and detect outliers [Liu et al., 2012]. To do this, the DBSCAN algorithm uses the inputs $minPts$, $radius(\epsilon)$ and a distance function [Schubert et al., 2017]. The ϵ is used to draw a neighborhood and the $minPts$ is used as a weight to evaluate which points should be inside the neighborhood. For the distance function, the Euclidean distance is used, to be consistent with the other algorithms.

Choosing radius(ϵ): The desired ϵ can be calculated using the K-NearestNeighbours algorithm [Ester et al.; Schubert et al., 2017]. The general approach for this is to choose a $K = 2 * N - 1$ (where N is the number of features) and plot the distance for each point. This can then be plotted using a k-dist plot and the best "elbow" can be chosen for deciding the ϵ (similar to choosing the k for K-means) [Elbatta and Ashour, 2013].

Figure 2.3: K-dist plot example for $minPts = 4$ based on a 2-dimensional dataset [Ester et al.]

Choosing minimum points ($minPts$): This hyperparameter is considered by a paper written by Sander et al. The work describes a way of calculating this parameter by doing two times the feature amount [Sander et al., 1998]. So, using this approach a dataset with two features will have an $minPts$ of four. This is confirmed by Schubert et al. to use the default $minPts$ = 4 for a 2-dimensional dataset [Schubert et al., 2017].

In conclusion, the parameters of DBSCAN are a little harder to estimate than for AP. But, as with K-means for k there exists a selection method the ϵ. Although DBSCAN requires the most hyperparameters out of the three clustering algorithms, determining them is clearer than for K-means. There are clear methods for determining both the $minPts$ and ϵ.

OVERFITTING
2.2.2. EVALUATION METHODS

Clustering comparison measures are important in cluster analysis for external validation by comparing clustering solutions to a "ground truth" clustering [Vinh et al.]. These external validity indices are a common way to assess the quality of unsupervised machine learning methods like clustering [Warrens and van der Hoef, 2022]. A method that could be used for this is the Rand Index [Rand, 1971]. It is a commonly applied method for comparing two different cluster algorithms [Wagner and Wagner]. An improvement of this method is adjusted for chance by considering the similarity of pairwise cluster comparisons [Vinh et al.]. Both the Rand Index (RI) and Adjusted Rand Index (ARI) [Hubert and Arabie, 1985] report a value between 0 and 1. Where 0 is for no-similarity and 1 for identical clusters. Alternatives for RI are the Fowles-Mallows Index and Mirkin Metric. However, these two methods have their disadvantages. Respectively, being sensitive to a few clusters and cluster sizes [Wagner and Wagner]. The ARI metric suffers from cluster size imbalance as well, so it only provides not a lot of information on smaller clusters [Warrens and van der Hoef, 2022]. Instead, they recommend using the cluster index metric that was proposed by Fränti et al. [Fränti et al., 2014].

Another popular group of methods is the information theoric-based measures [Vinh et al.]. This metric measures the information between centroids; the higher the value, the better [Vinh et al.]. Mutual Information (MI) is such metric, which calculates the probability of an element belonging to cluster C or C'. But, is not easy to interpret as it does not have a maximum value [Wagner and Wagner]. To this end, Normalized Mutual Information (NMI) can be used to report a value between 0 and 1 using the geometric mean [Strehl and Ghosh, 2002]. The metric exists also in an adjusted version as Adjusted Mutual Information (AMI). This works in the same way as for the Adjusted Rank Index (ARI) and is mostly needed if the number of data items is small in comparison to the number of clusters [Vinh et al.].

Besides the external validity measurements for clustering, it is also possible to use internal validation methods. These metrics focus entirely on the intrinsic dataset properties, instead of relying on an external baseline cluster algorithm Craenendonck and Blockeel. Assessing two important concepts of clustering: compactness and separation Hassani and Seidl [2017]. Both studies, consider three different metrics and measure both concepts at the same time Hassani and Seidl [2017]:

1. Calinski-Harabasz Index (CHI) [Caliński and Harabasz, 1974] is used to measure the cluster variance (well-separated clusters) and low variance within the clusters (tightly coupled data). A high score indicates better clustering.

2. Silhouette Index [Rousseeuw, 1987] this metric is similar, by also measuring cohesion within clusters and separation of clusters. However, this metric uses the pairwise distance Hassani and Seidl [2017]. A score of -1 indicates incorrect clustering and +1 for dense clusters Rousseeuw [1987].

3. Davies-Bouldin [Davies and Bouldin, 1979] uses the average distance between centroids. A lower score indicates good clustering.

K-Means scores relatively high for CHI [Craenendonck and Blockeel; Hassani and Seidl, 2017] and SI [Craenendonck and Blockeel]. The same applies to DBSCAN, which scores relatively high on SI and DB due to the sensitivity of noise Craenendonck and Blockeel.

EXISTING LITERATURE

Comparable studies with differential privacy use external validation [Sun et al., 2022; Xia et al., 2020]. Their experiment setup uses a so-called non-private cluster algorithm as external validation. This cluster algorithm is trained without the perturbed data and compared with the same clustering algorithm that is trained with perturbed data. Thus, the non-private variant functions as an external validation by providing the ground truth.

They compare the mutual information between a baseline cluster algorithm using AMI [Huang et al., 2021] or NMI [Sun et al., 2022; Xia et al., 2020]. Another study for evaluating Differential Privacy (DP) with AP uses both ARI and AMI. In addition to mutual information and rand index scores, it is also not uncommon to calculate the error between the two cluster algorithm's centroids [Huang et al., 2021; Xia et al., 2020]. These two studies used Relative Error (RE) for this.

ND-LAPLACE

</div>

3.1. 2D-LAPLACE

The theory for this subject is heavily inspired by the paper that was written by Andrés et al. [Andrés et al., 2012]. This notion of Geo-indistinguishability (GI) was introduced to solve the issue of privacy and location data. It offers an alternative approach for differential privacy by adding noise to the location locally before sending it to a location-based system (LBS) like Google maps. This section starts with an introduction to mathematics for the planar and polar Laplace algorithm. For each of the different subsections, we visualize and explain open challenges and theoretic for applying them for clustering.

MATH SYMBOLS

θ Angle.

l Privacy level.

r Radius.

The other symbols can be found in section 2.1.

GEO-INDISTINGUISHABILITY

As mentioned in the previous section, the GI method can be applied to preserve the privacy using a differential privacy method specific to spatial data. The formula to measure if an algorithm preserves ϵ-geo-indistinguishability can be expressed as [Andrés et al., 2012]:

$$K(x)(y) \le e^{\epsilon * d(x,x')} K(x')(y) \tag{3.1}$$

Where K is a probability method reporting $x, x' \in X$ as $z \in Z$. The idea of this algorithm looks a lot like that of differential privacy using the La Place method; but includes distance. The intuition for this is that it displays the distinguishability level between two secret locations/points x and x' [Chatzikokolakis et al., 2015]. An extension of this is called d_x-privacy and is a more general notation of distance-aware differential privacy. Their definition for GI is, therefore, d_2-privacy, but is essentially the same as the proof provided for GI.

3.1.1. PLANAR AND POLAR LAPLACE

The idea of planar Laplace is to generate an area around $x0 \in X$ according to the multivariate Laplace distribution. The mechanism of planar Laplace is a modification of the Laplace algorithm to support distance [Andrés et al., 2012]. This distance method $dist(x, x')$ is defined as the Euclidean distance between two points or sets. Recalling the definition of Laplace, this method $|x - x'|$ is replaced by the distance metric. Hence, the definition of the Probability Density Function (pdf) by Andrés et al. is:

$$\frac{\epsilon^2}{2 * \pi} e(-\epsilon d(x_0, x)) \tag{3.2}$$

Which is the likelihood a generated point $z \in Z$ is close to $x0$. The method works for Cartesian coordinates but was modified to support polar coordinates by including θ. So each point is reflected as (r, θ) and can be modified by using a slight modification to work for polar Laplace. A point $z \in Z$ where $z = (r, \theta)$ is randomly generated using two separate methods for calculating r and θ.

Figure 3.1: Representation of the generated $z = r\theta$ and original point $x0$.

Calculating r: This variable is described as $dist(x_0, z)$ and can be randomly drawn by inverting the CDF (**Link**) for the Laplace distribution:

$$C_\epsilon^{-1}(p) = -\frac{1}{\epsilon}(W_{-1}(\frac{p-1}{e}) + 1)$$

(3.3)

For this equation, W_{-1} is a Lambert W function with -1 branch. The Lambert w function, also called the product logarithm is defined as $W(x)e^{W(x)} = x$ [Lehtonen, 2016]. The purpose of the Lambert w function is to invert the CDF of the Laplace distribution to generate random noise for one of the coordinates (r) using the random value of p.

Calculating θ: The other coordinate (θ) is defined as a random number $[0, 2\pi]$.

To visualize these methods it is necessary to convert the polar coordinates for $z = (r, \theta)$ back to a plane (x, y). This is described as step 4 of the planar Laplace algorithm [Andrés et al., 2012] and visualized using figure **??**.

Figure 3.2: Representation of converting the perturbed point $z = (r, \theta)$ to a point z_x, z_y

3.1.2. TRUNCATION

Because we have a finite space, it can be possible the perturbed points are off-graph (outside the given domain). The solution was described in step 5 of the Laplacian mechanism for 2D space. This explains the idea of remapping to the closest admissible location in set A. For which $A \subset \mathbb{R}$, where A is the set of admissible locations [Andrés et al., 2012]. This is also described by chatzikokolakis et al, who also describes a method to do it. When a perturbed point z is located at the sea or in water, it is easily distinguishable as a fake location. They introduce a method to check this and efficiently remap to a nearby location.

> Describe the method

> Analyze other methods

3.1.3. OPTIMIZING FOR CLUSTERING

The decision of the parameters for the algorithm is straightforward as it depends on the ϵ. This constant is calculated by defining the radius r and the desired level of privacy l and ϵ is calculated using l/r. The l is a predefined constant $l \in R^+$ but usually will be below 10. For geographical data, the r can be configured by using meters as a unit of measure. Therefore, $r = 200$ corresponds to a radius of 200m around point x_0. So, regarding clustering, it is a challenge to define a reasonable radius.

The ϵ can be considered the inverse unit of r [Andrés et al., 2012]. A radius can be defined per-use case based on how crowded a place is [Chatzikokolakis et al., 2015].

> Give the algorithm

A drawn area as shown in **??** can be expressed as a perturbation area P_{area} [Yan et al., 2022]. This metric was formulated as:

$$P_{area} = \left\{ center = x_0, radius = \frac{1}{N} \times \sum_{i=1}^{N} r_i \right\} \tag{3.4}$$

The method loops through each perturbed point r on center x_0 (recall **??**) and calculates the Euclidean distance for an n amount of perturbation points. Although the method does not contribute to the Laplace algorithm, it is useful for visualization purposes.

Is considered for research question 2

3.3. nD-Laplace

Is considered for research question 2

ATTACKS ON PRIVACY

4.1. MEMBERSHIP INFERENCE ATTACKS

An attack model that plays a big role in machine learning is a membership inference attack. With this attack, an adversary attempts to infer the original data point $x \in X$ from a given data point $z \in Z$. The adversary has access to a point z, the size of the dataset $|Z|$ and a distribution D where Z was drawn from [Yeom et al., 2018]. These attacks depend on the adversarial knowledge, which can be divided into white-box and black-box MIA's [Hu et al., 2022].

1. **White-box**: The attacker has all the data that is needed. Including target model parameters, the training dataset and even the architecture [Hu et al., 2022].

2. **Black-box**: The attacker has a limited amount of information, like training data distribution and the trained model [Hu et al., 2022].

An approach called *Binary classifier membership inference attacks* is used to separate members from non-members. [Hu et al., 2022]. This method evolves around the attacker generating a shadow model, with as goal to overfit [Shokri et al., 2017]. If the data is fed with real data the score is higher than similar data, which means the real data can be inferred [Jayaraman and Evans; Shokri et al., 2017] A white-box setting requires a lot of adversarial knowledge for training the shadow models. The black-box settings only take the prediction as input and decide if it is a (non-) member [Hu et al., 2022]. An unsupervised black-box MIA was introduced by Peng et al. and only considers that the attacker has access to the already trained model. They rescale the probabilities first using temperature scaling, to compensate for models that are overconfident [Peng et al.]. So instead of having a probability between two classes with for example 99% against 1% it will be more evenly distributed based on the training data. They then proceed in clustering the probabilities into two clusters using K-Means and label the higher confidence scores as members.

The above attacks do rely on the model to also provide the confidence or probabilities of the predictions. This is often not the case for the practical appliance of a model, and therefore Choquette-Choo et al. introduced a label-only attack. While the existing models exploit the probability output for MIA, they solely rely on labels. For this, they make use of the "HopSkipJump" attack; a so-called decision-based attack [Chen et al., 2020]. Choquette-Choo et al. consider a more semi-black-box approach, for which the attacker still requires access to a subset of the original training data and the trained model. Another paper that also uses "HopSkipJump" requires only the trained model and achieves higher accuracy by using an approach with random data [Li and Zhang, 2021].

Another take on this is prediction and confidence-based MIA which are both proposed by [Yeom et al., 2018]. They assume that an attacker knows the standard error and has access to the perturbation dataset. The algorithm is then able to extract the truth label by minimizing the loss.

Write summary / conclusion

escribe how dp
used to pro-
ct MIA

Figure 4.1: Semi-supervised membership inference attack considering a black-box approach [Chen et al., 2020; Li and Zhang, 2021]

4.2. RECONSTRUCTION ATTACK

This attack is a threat, especially to differential privacy. The attack is primarily focused on reconstructing the data rather than focusing on machine learning.

5

METHODOLOGY

To gain insights into the proposed methods for researching the appliance of (ND)-Laplace for cluster algorithms we conducted experiments. The experiment results are used to evaluate our method against other literature. In this chapter we explain:

1. Datasets

2. Environmental setup.

3. For each research question: Description of the different experiments.

4. For each research question: Results.

5.1. DATASETS

For this research, we will use a synthetic dataset for all three research questions. In addition to this, we used the LSun dataset as a lot of comparable literature uses this as well for evaluation.

Describe LSun dataset

Dataset	Records	Centers	Dimensions	Standard deviation	Research
1	50	4	2	0.60	RQ 1
2	50	4	3	0.60	RQ 2
3	50	4	5	0.60	RQ 2

Research question 3 uses a "real-world" dataset to properly assess the different dataset properties that are the subject of this research question.

Describe datasets (RQ3)

5.2. ENVIRONMENTAL SETUP

For running the experiments we make use of 16GB ram memory and i7-10750H 2.6Ghz processor. The experiments are run using a Docker container which runs a pre-configured distribution of Linux Alpine. It includes a pre-installed Anaconda environment for python [1,2]. We run the container using the dev-container feature for visual-studio code [3]. This allows us to create a reproducible experiment environment.

---

[1] https://github.com/devcontainers/images/tree/main/src/anaconda
[2] tag: mcr.microsoft.com/devcontainers/anaconda:0-3
[3] https://code.visualstudio.com/docs/devcontainers/containers

5.2.1. LIBRARIES & CODE VERSIONS

We use python version 3.9.13 with Jupyter notebook for creating a reproducible experimental environment. The packages for python are:

1. Scikit-learn: 1.0.*

2. Yellow-brick: 1.5

3. Numpy: 1.24.*

4. Pandas: 1.4.*

5. Seaborn: 0.11.*

6. Mathplotlib: 3.5.*

5.3. METHODS

This section explains what methods/ algorithms we used and how we evaluate them.

5.3.1. CLUSTERING METHODS

For the three different algorithms: K-Means, AP and DBSCAN we analyzed the most important decisions regarding parameter selection. In this section, we give a short list and explanation of the different parameters we used throughout the experiments. For all three Sklearn was used, and for each of them we also provide the underlying formula.

5.3.2. EVALUATION

With differential privacy, it is a trade-off of utility versus privacy. Therefore, for the evaluation of the 2D/3D-Laplace algorithms, we compare both criteria to achieve a consensus between utility and privacy.

UTILITY

Based on chapter 2.2.2, we can conclude that the corresponding literature mainly evaluates one clustering algorithm and not multiple ones. Because of this, we do not use any internal validation; because the different types of metrics are too easily influenced by the choice of clustering algorithm. Instead, we decided to pick up external validation methods similar to other studies as well. They did use either Rand Index or Mutual Information, but because both have different strengths we evaluate both.

It is not likely that we will use many data points for research questions 1 and 2. To compensate for this, the adjusted version is used for both Rand Index and Mutual Information. Since both Mutual Information and Rand Index have different characteristics in the type of clustering algorithm, we use both. To reduce the possible bias of results we executed them 10 times for multiple privacy budgets and report the average for each [Huang et al., 2021].

Finally, the implementation for these metrics is provided by the Scikit-learn package. With the underlying formulas:

$$AMI(U,V) = \frac{MI(U,V) - E(MI(U,V))}{avg(H(U),H(V)) - E(MI(U,V))} \tag{5.2}$$

Adjusted Mutual Information formula [Hubert and Arabie, 1985; Vinh et al.]

$$RI = \frac{a+b}{C_2^n} \tag{5.3}$$

$$ARI = \frac{RI - E(RI)}{max(RI) - E(RI)} \tag{5.4}$$

(Adjusted) Rand Index formula [Hubert and Arabie, 1985; Rand, 1971]

PRIVACY

The most important one here is the preserving of GI according to the formula 3.1. This validates that we applied the algorithms in the right way and automatically inherit the strong privacy guarantees provided by GI. A disadvantage of this method is that it cannot be used to achieve a clear representation of privacy (it is either "yes" or "no"). Therefore, we analyze our method according to a popular attack: Membership inference attack.

For this purpose, we make use of a black-box Member inference attack, called "Hop-SkipJump" [Chen et al., 2020; Li and Zhang, 2021]. This attack is evaluated using a semi-supervised setup, as proposed in this figure: **??**. We will make use of a decision tree model

for classification but can be replaced by any other classification model. Both the private and non-private trained models are evaluated based on the true positive rate (TPR) and false positive rate (FPR). Respectively meaning, the TPR is higher if the MIA is successful and likewise the FPR if the MIA is unsuccessful. We hypothesize that the private model leverages a higher FPR in comparison to the non-private variant.

5.3.3. SCALING

Because we use a distance metric, we need to apply some data standardization. For this purpose, we use standard scaling provided by the Scikit-learn package [4]. This is only for clustering, so it is applied after all the perturbation algorithms.

5.3.4. RESEARCH QUESTION 1

TRUNCATION:

We explained the theory for truncation earlier in paragraph 3.1.2. The methods proposed work correctly for a geographic map where other (historic) locations for remapping are available.

However, it is difficult to apply this to data clustering. The number of data points is not known beforehand, so we may remap to a location that is too far away. This way we lose important distance information, which hurts the clustering. Also, the truncation threshold is so clear (the points are outside the known 2D domain), that we do not have to rely on historical data for remapping. Our algorithm can be much simpler by re-calculating the noise until it will be within the domain:

Algorithm 1 Truncation algorithm ($T(\min, \max, x_0, z)$) for clustering with planar Laplace

---
Ensure: z
  $x_1, y_1 \leftarrow x_{min}$
  $x_2, y_2 \leftarrow x_{max}$
  $z_x, z_y \leftarrow z$
  if $x_1 < z_x < x_2$ and $y_1 < z_y < y_2$ **then**
      return z
  else
      $x, y \leftarrow x_0$
      $z_2 \leftarrow LP(\epsilon, x, y)$ ▷ See formula 3.3.
      return $T(x_{min}, x_{max}, x_0, z_2)$ ▷ Rerun recursively
  end if

This algorithm uses x_{min} and x_{max} to re-calculate the points within the domain using respectively the minimum X/Y and maximum X/Y. An example of this is visualized:

Figure 5.1: Representation of the remapping algorithm for clustering for points z_3 and z_4

The full algorithm for the perturbation:

Algorithm 2 Full algorithm for perturbing cluster data based on planar/2D-Laplace [Andrés et al., 2012]

Require: $x \in X$ ▷ 2D array of points

Require: $l \in R^+$

Ensure: $z \in Z$ ▷ 2D array of perturbed points

   $r = \frac{\sigma}{2}$ ▷ formula 4.1

   $\epsilon = \frac{l}{r}$ ▷ Calculating privacy budget [Andrés et al., 2012]

   $x_{min} \leftarrow min(X)$

   $x_{max} \leftarrow max(X)$

   $Z \leftarrow []$

   for $point_i \in X$ **do**

      $\theta \leftarrow [0, \pi 2]$ ▷ Random noise for θ

      $p \leftarrow [0, 1]$

      $z_i \leftarrow C_\epsilon^{-1}(p)$ ▷ formula 3.2

      $z_i \leftarrow T(x_{min}, x_{max}, point_i, z_i)$ ▷ algorithm 1.

      $x_{perturbed} \leftarrow point_{i_x} + (z_{i_x} * \cos(\theta))$ ▷ add noise to x-coordinate

      $y_{perturbed} \leftarrow point_{i_y} + (z_{i_y} * \sin(\theta))$ ▷ add noise to y-coordinate

      append $x_{perturbed}, y_{perturbed}$ to Z

   end for

   return Z
